4. Example: Korsbetningen
The frequentist approach to statistics is characterized as follows.

- Data $y$ is viewed as an observation of a random variable $Y$ with distribution $\mathbb{P}_0$ which most often is assumed to be a member of an exponential family

$$\mathcal{P} = \{\mathbb{P}_\theta; \theta \in \Theta\}.$$ 

- Estimates $\hat{\theta}(y)$ are realizations of random variables.
- Confidence intervals are calculated to cover the true value in, say, 95% of the cases.
- Hypothesis testing is done by rejecting a hypothesis $\mathcal{H}_0$ if $\mathbb{P}(\text{data}|\mathcal{H}_0)$ is small.
The Bayesian approach

Briefly, the Bayesian approach to statistics is as follows.

- The parameter $\theta$ is viewed as a random variable, and inference is based completely on the posterior distribution $f(\theta|y)$.
- It is possible to incorporate prior information in terms of the prior distribution $f(\theta)$.
- A 95% credible or posterior probability interval contains $\theta$ with a probability of 95% given the observations.
- Hypothesis tests are done by studying $\mathbb{P}(\mathcal{H}_0||\text{data})$. 
1. Last time: Stochastic modeling and Bayesian inference
2. Example: Change point detection
3. Interlude: Mixing of MCMC samplers
4. Example: Korsbetningen
Consider the following model.

- We have measured the waiting times in a system and suspect that the expected waiting time changed during the monitoring period.
- The observations $y_i$ for $i = 1, \ldots, n$ are assumed to follow exponential distributions with parameter $\theta_1$ for $i \in \{1, \ldots, n_b\}$ and parameter $\theta_2$ for $i \in \{n_b + 1, \ldots, n\}$.
- Further, we put a Gamma prior on $\theta_k$, $\theta_k \sim \Gamma(a, b)$, with $a = 40$ and $b = 4$, and a uniform prior on $n_b$. 

![Graph showing waiting times over time](image-url)
Thus, we have unknown parameters \((\theta_1, \theta_2, n_b)\) and data \(Y = (y_1, \ldots, y_n)\). The posterior becomes

\[
f(n_b, \theta_1, \theta_2 | y_1, \ldots, y_n) \\
\propto f(n_b, \theta_1, \theta_2, y_1, \ldots, y_n) \\
= f(\theta_1)f(\theta_2)f(n_b) \prod_{i=1}^{n} f(y_i | n_b, \theta_1, \theta_2) \\
= \theta_1^{n_b+a-1} \exp\left(-\theta_1 \left(b + \sum_{i=1}^{n_b} y_i \right)\right) \\
\times \theta_2^{n-n_b+a-1} \exp\left(-\theta_2 \left(b + \sum_{i=n_b+1}^{n} y_i \right)\right),
\]
The conditional distributions of $\theta_1$ and $\theta_2$ are easily calculated according to

$$\theta_1|n_b, \theta_2, y_1, \ldots, y_n \sim \Gamma \left( n_b + a, b + \sum_{i=1}^{n_b} y_i \right),$$

$$\theta_2|n_b, \theta_1, y_1, \ldots, y_n \sim \Gamma \left( n - n_b + a, b + \sum_{i=n_b+1}^{n} y_i \right).$$

The conditional distribution of $n_b$ is however more complicated:

$$f(n_b|\theta_1, \theta_2, y_1, \ldots, y_n)$$

$$\propto \theta_1^{n_b} \exp \left( -\theta_1 \sum_{i=1}^{n_b} y_i \right) \theta_2^{-n_b} \exp \left( -\theta_2 \sum_{i=n_b+1}^{n} y_i \right)$$
Example: Change point detection (cont.)

Thus, we sample the posterior of \((\theta_1, \theta_2, n_b)\) using a Gibbs sampler with a MH step for \(n_b\), yielding a hybrid sampler. The MH step goes as follows.

Given \(n_b\), we propose a candidate \(n^*_b\) uniformly on the integers \(\{n_b - R, \ldots, n_b, \ldots, n_b + R\}\), for some \(R\). This forms a symmetric proposal on \(\{1, \ldots, n\}\).

The acceptance probability for the MH step thus becomes

\[
\alpha(n_b, n^*_b) = 1 \wedge \frac{\theta_1^{n^*_b} \theta_2^{-n^*_b} \exp(-\theta_1 \sum_{i=1}^{n^*_b} y_i) \exp(-\theta_2 \sum_{i=n^*_b+1}^{n} y_i)}{\theta_1^{n_b} \theta_2^{-n_b} \exp(-\theta_1 \sum_{i=1}^{n_b} y_i) \exp(-\theta_2 \sum_{i=n_b+1}^{n} y_i)}.
\]
Running this Gibbs sampler with $R = 75$ gives an acceptance rate of 33%.
The resulting histograms of the parameters are as follows:

- $N_b$
- $\theta_1$
- $\theta_2$
- $\theta_1, \theta_2$
Selecting priors

The posterior is computed via Bayes’s formula

\[
f(\theta|y) = \frac{f(y|\theta)f(\theta)}{\int f(y|\theta')f(\theta')d\theta'} \propto f(y|\theta)f(\theta).
\]

In Bayesian modeling there is always an interplay between the prior and the data:

- The posterior is drawn away from the data towards the prior. How far depends on the strength of the prior.
- However, enough data will most likely overwhelm the prior.

Two common prior-types are

- conjugate priors.
- improper (flat) priors.
Conjugate priors

- are such that the prior and the posterior belong to the same distribution class for a given likelihood.
- allow theoretical calculations and Gibbs sampling.
- are sometimes criticized since we select priors for ease of calculation. However, often the parameters are flexible enough to allow for a reasonable prior.
- may be hard to derive for complex models.
Conjugate priors for $\theta$ for some common likelihoods. All parameters except $\theta$ are assumed fixed and known and data $(y_1, \ldots, y_n)$ is assumed to be conditionally independent given $\theta$.

Improper priors

Improper, or flat, priors are used when prior information is deficient.

For instance, if $\theta \in \mathbb{R}$, $f(\theta) \propto 1$ is an improper prior since it is not integrable; however, we allow this as long as the posterior is a well-defined density.

For instance, let $y$ be an observation from $Y \sim \mathcal{N}(\theta, 1)$, where $\theta \in \mathbb{R}$. Since we do not have any prior information concerning $\theta$ we put $f(\theta) \propto 1$ for all $\theta \in \mathbb{R}$. After this we proceed, formally, like

$$f(\theta|y) = \frac{f(y|\theta)f(\theta)}{\int f(y|\theta')f(\theta') \, d\theta'} = \frac{\mathcal{N}(y; \theta, 1) \cdot 1}{\int \mathcal{N}(y; \theta', 1) \cdot 1 \, d\theta'} = \mathcal{N}(\theta; y, 1).$$

Mixing of MCMC samplers

We recall that the asymptotic variance of $\tau_N$ is given by

$$\sigma^2 = r(0) + 2 \sum_{\ell=1}^{\infty} r(\ell) \quad \text{with} \quad r(\ell) = \lim_{n \to \infty} \mathbb{C}(\phi(X_{n+\ell}), \phi(X_n)).$$

Some remarks:

- Consequently, in order to obtain a low variance of $\tau_N$, the covariance function $r(\ell)$ should decrease rapidly with $\ell$.
- For geometrically ergodic chains $r(\ell)$ tends to zero geometrically fast.
- The speed of which $r(\ell)$ tends to zero is typically described using the term mixing.
  - Strong mixing = fast forgetting = rapidly decreasing $r(\ell)$.
  - Bad mixing = slow forgetting = slowly decreasing $r(\ell)$.
Why is good mixing important?

Bad choices of proposal distributions may lead to bad mixing, implying high variance and the need of a large MC sample size to ensure good estimates. This causes problems for the MCMC algorithm in the sense that it may

- fail to converge altogether or
- need a very long time to converge.
Optimal mixing

Let us focus for a while on the MH algorithm.

- When designing a random walk proposal, \( X_k^* = X_k + \epsilon \) with \( \epsilon \sim \mathcal{N}(0, s\Sigma) \), two things will effect the acceptance rate:
  1. How well \( \Sigma \) captures the dependence of the target distribution.
  2. How appropriate the scaling \( s > 0 \) is.

- One way to obtain a covariance matrix \( \Sigma \) that captures well the dependence structure of the target distribution \( f(x) \) is to let

\[
\Sigma_{ij} = \frac{2.38}{d} \left( - \frac{\partial^2 \log f(x)}{\partial x_i \partial x_j} \bigg|_{x=x_{\text{mode}}} \right)^{-1}.
\]

- Rule of thumb: A good acceptance rate is around 30% (23%–44%).
Using symmetric normal proposal with three different values for \( s \) (small, medium, large, respectively) yields the following trajectories:
Mixing—Random walk proposal

Example: Korsbetningen

We are here → •
I Herrens år 1361, tredje dagen efter S:t Jacob, föll utanför Visbys portar gutarna i danskarnas händer. Här är de begravda. Bed för dem.

On the third day after saint Jacob, in the year of our lord 1361, the Goths fell outside the gates of Visby at the hands of the Danish. They are buried here. Pray for them.
The background is the following.

- In 1361 the Danish king Valdemar Atterdag conquered Gotland and captured the rich Hanseatic town of Visby.
- Most of the defenders were killed in the attack and are buried in a field, Korsbetningen, outside of the walls of Visby.
- In 1929–1930 the gravesite and was excavated. A total of 493 femurs, 237 right and 256 left, were found.
- We want to estimate the number of buried bodies.
- A interesting tv-programme (in Swedish) about the event can be found at http://www.oppetarkiv.se/video/1070393/hermans-historia-sasong-3-avsnitt-2-av-5
Example: Korsbetningen—model

We set up the following model.

- Assume that the numbers $y_1$ and $y_2$ of left resp. right legs are two observations from a $\text{Bin}(n, p)$ distribution.
- Here $n$ is the total number of people buried and $p$ is the probability of finding a leg, left or right, of a person.
- We put a conjugate $\text{Beta}(a, b)$-prior on $p$ and a $\mathcal{U}(256, 2500)$ prior on $n$. 

![Graph showing distributions](image)
Example: Korsbetningen—a hybrid MCMC

We proceed as follows:

- A standard Gibbs step for

\[ p|n, y_1, y_2 \sim \text{Beta}(a + y_1 + y_2, b + 2n - (y_1 + y_2)) \].

- MH for \( n \), with a symmetric proposal obtained by drawing, given \( n \), a new candidate \( n^* \) among the integers \( \{n - R, \ldots, n, \ldots, n + R\} \).

- The acceptance probability becomes

\[ \alpha(n, n^*) = 1 \wedge \frac{(1 - p)^{2n^*}(n^*)^2(n - y_1)!(n - y_2)!}{(1 - p)^{2n}(n!)^2(n^* - y_1)!(n^* - y_2)!} \].
Example: Korsbetningen—a hybrid MCMC
